Abstract

Purpose: While the intention of endurance athletes undertaking short term heat training protocols is to rapidly gain meaningful physical adaption prior to competition in the heat, it is currently unclear whether or not this process also presents an overt, acute challenge to the immune system. The aim of this study was therefore to examine the effects of heat training on both endurance performance and biomarkers associated with inflammatory and immune system responses. Methods: Moderately-actively males (n=24) were allocated randomly to either HOT (n=8, 35°C and 70% RH; NEUTRAL (n=8, 20°C and 45% RH); or a non-exercising control group, (CON, n=8). Over the 18 day study HOT and NEUTRAL performed seven training sessions (40 min cycling at 55% of VO2 max) and all participants completed three heat stress tests (HST) at 35°C and 70% RH. The HST protocol comprised three x sub-maximal intervals followed by a 5 km time trial on a cycle ergometer. Serum samples were collected before and after each HST and analysed for interleukin-6, immunoglobulin M and lipopolysaccharide. Results: Both HOT and NEUTRAL groups experienced substantial improvement to 5 km time trial performance (HOT -33 ± 20 s, p = 0.02, NEUTRAL -39 ± 18 s, p = 0.01) but only HOT were faster (-45 ± 25 s and -12 s ± 7 s, p = 0.01) in HST3 compared to baseline and HST2. Interleukin-6 was elevated after exercise for all groups however there were no significant changes for immunoglobulin M or lipopolysaccharide. Conclusions: Short-term heat training enhances 5 km cycling time trial performance in moderately-fit subjects by ~6%, similar in magnitude to exercise training in neutral conditions. Three top-up training sessions yielded a further 3% improvement in performance for the HOT group. Furthermore, the heat training did not pose a substantial challenge to the immune system.

Key words: cycling, heat acclimation, inflammation, lipopolysaccharide, cytokine, endurance performance
Introduction

Short- and medium-term heat acclimation training protocols are widely used by endurance athletes to increase both heat tolerance and subsequent competitive performances in the heat (Périard, Racinais, and Sawka. 2015). Although favourable performance and physiological benefits can be realized from short term programs (<7 days), greater benefits are likely from longer protocols (7-14 days) (Daanen et al., 2011; Guy, et al. 2015; Lorenzo et al. 2010; Nielsen et al. 1997). For elite athletes, busy training and performance schedules limit the time available for strategies such as heat training, and addition of supplementary training sessions may sustain and/or complement the initial adaptations.

While the acute effects of short-term heat exposure on blood biomarkers associated with inflammation have been reported (Gill et al. 2015; Hailes et al. 2011), few studies have investigated the effects of longer duration heat training. The human immune system can usually deal with mild-to-moderate inflammatory responses, however, when a heat stimulus is too large, systemic inflammation can result in heat shock and potentially fatal sepsis (Bouchama et al. 2007). Athletes will generally seek a heat training stimulus that is large enough to evoke a training adaptation; however, there likely comes a point where the risk of clinical or subclinical levels of immune disturbance increases.

Exercise-induced endotoxemia is a potential risk of strenuous activity in the heat primarily attributed to translocation of lipopolysaccharide (LPS) from the gut into the circulation (Lim et al. 2009). An abundance of circulating LPS can evoke an inflammatory response, leading to heat shock and overwhelming anti-LPS mechanisms including immunoglobulin M (IgM) (Camus, et al. 1998) and cytokines operating in an anti-inflammatory role such as interleukin-6 (IL-6) (Abbasi et al. 2013). Consequently, when anti-LPS mechanisms and rate of LPS clearance are inadequate to counter the heat-induced increase of LPS, endotoxemia may ensue. This outcome could potentially occur during a period of heat acclimation training if the athlete is unable to cope with the thermal loads presented. As IgM is a key antibody in neutralising LPS (Camus et al., 1998), its concentration in circulating blood can reflect the body’s response to endotoxin accumulation, and the degree of protective capacity in the event of further challenges. IgM concentration can increase substantially (~20%) after exercise in the heat, although this elevation does not occur following five days of heat training (Hailes, et al. 2011). Of the few studies that have investigated IL-6 as a blood biomarker during exhaustive exercise in the heat, Selkirk and colleagues (2008) observed a twenty-fold increase in plasma concentrations following 2 h of exhaustive walking in protective clothing in very hot and humid conditions, with IL-6 inhibiting endotoxin induced increases in tumor necrosis factor alpha and cytokines. Furthermore, the neuroinflammatory response to exercise indicates that an increase in cytokine concentration such as IL-6 reaching a critical threshold, it is likely that sensations of fatigue develop to prevent traumatic injury of specific organs and other physiological systems within the body (Vargus & Marino, 2014) Therefore, athletes who undertake short or medium duration heat acclimation training programs could potentially be at increased risk of exercise-induced heat stress and immune disturbances associated with fatigue.

Recreationally-active healthy adults often participate in one-off events such as an ironman triathlon, marathon and week-long sporting events such as the Masters’ Games. It appears that the threshold for the onset of exercise-induced endotoxemia is lower in untrained than trained individuals (Selkirk et al. 2008). Individuals seeking to use heat acclimation training as an additional training stimulus may choose either a short- or medium-term program, to elicit the classic thermal markers of plasma volume expansion, lower heart rate at
submaximal intensities and lower end point core temperature, which collectively promote
aerobic performance (Guy et al, 2015). However addition of a heat load to training can often
be very demanding, with some studies implementing challenging protocols on their
participants, e.g. 90 min of cycling for 10 consecutive days (Gibson et al. 2015). It is prudent
to account for both training load and accumulated inflammation from heat stress over the
training period. As longer heat training sessions (>60 min) are likely fatiguing for
recreationally-trained athletes, and can increase peripheral fatigue compared with shorter
protocols (Wingfield et, 2016), the addition of shorter and supplementary training sessions
could yield similar benefits, but with lower overall stress.

Few studies have investigated the degree of inflammation and endotoxemia associated with
short- and medium-term heat acclimation training. Therefore, the aim of this study was to
investigate whether short-term heat training with the addition of supplementary sessions can
improve cycling time trial performance (TT), improve sub-maximal exercising heart rate and
core temperature, and to quantify the degree of inflammation associated with heat
acclimation training.

**Methods**

**Design**

This study consisted of three groups of recreationally-active male athletes: a heat training
group (HOT), a matched thermo-neutral training group (NEUTRAL) and a control (no
training) group (CON), in a pre-post parallel groups design.

**Participants**

Twenty four moderately trained male participants (3 ± 1 moderate-high intensity training
sessions per week, duration 60 ± 15 mins; mean ± SD) aged 24.5 ± 3.8 years, height 178 ± 7
cm, mass 84.6 ± 10.8 kg, body fat 17.5 ± 6.1%, and maximal oxygen uptake (\(\dot{V}O_2\max\)) of
45.0 ± 5.0 ml.kg.min\(^{-1}\) volunteered for the study. Prior to taking part, participants provided
written informed consent in accordance with the Declaration of Helsinki and underwent a
pre-screening health questionnaire including use of anti-inflammatory or immunomodulating
medications (none were present). The study protocol was approved by the James Cook
University Human Research Ethics Council (Approval number H5647).

**Methodology**

Assessment of \(\dot{V}O_2\max\) was undertaken on a cycle ergometer (VeloTron and Velotron
Coaching Software, Racermate, United States) at least 72 h before beginning the
experimental trials. The intervention comprised a short-term training protocol of four training
sessions on consecutive days, followed by three supplementary training sessions every three
days. All participants completed three heat stress tests (HST\(_{1,3}\)) and seven training sessions
over 18 days, with HST\(_1\) performed as a baseline measure of heat tolerance, HST\(_2\) completed
between the end of the short-term program and before beginning the supplementary top-up
training, and HST\(_3\) completed 48 hours after the final supplementary training session (Figure
1). Each group performed the HST in a custom-built environmental chamber at a temperature
of 35°C and 70% RH. Participants in the HOT and NEUTRAL conditions completed exercise
training sessions in hot and humid (35°C and 70% RH) or thermo-neutral conditions (20°C
and 50% RH) respectively. Participants in the CON group did not undertake exercise training
but completed the three HST’s at the same intervals as HOT and NEUTRAL groups.
Participants were instructed to rest and avoid moderate or high levels of physical activity on
days that they were not required to attend the laboratory.
Test of Maximal Oxygen Uptake
Maximal oxygen uptake was determined by an incremental test to exhaustion on a cycle
ergometer (VeloTron and Velotron Coaching Software, Racermate, United States). Briefly,
the test began with participants cycling at 80-90 rpm at 120 W, with the workload increasing
by 20 W every min until volitional exhaustion or when cadence was unable to be maintained
above 80 rpm. Expired gases were collected via a one-way breathing system (Hans-Rudulph,
United States) and analysed by a calibrated Moxus Metabolics Measurement cart (AEI
Technologies, United States). Attainment of $\dot{V}O_2_{\text{max}}$ was determined by the satisfaction of
standard criteria (Midgley et al. 2007).

Heat Stress Test
The heat stress test was of similar design to earlier work (Garrett et al. 2009; Lorenzo et al.
2010) and comprised cycling for three x 10 min submaximal workloads with a 3 min rest
period between workloads, followed by a 5-km self-paced time trial (TT). Following a 5 min
standardised warm-up, the participants completed three 10 min workloads at 50%, 60% and
70% of their peak wattage corresponding to their individualised $\dot{V}O_2_{\text{max}}$. After the 70%
workload was complete, a 5 min rest period was given before the start of the TT. Participants
were able to view their rpm and were informed of the distance travelled every 500 m to assist
with pacing. Heart rate (RS400, Polar Elektro, Finland), and core temperature ($T_c$) (ttec 501-3
data logger and data logger software version 10.1, Nordex Pty Ltd, Australia; MEAS 449 1RJ
rectal temperature thermistor, Measurement Specialities, United States) were sampled at 5 s
intervals. Fluid intake (water, ad libitum), rating of perceived exertion (Borg RPE 6 – 20,
Borg 1970) and thermal comfort (TComf) were recorded throughout the test. Nude dry body
mass was recorded pre and post exercise on a calibrated set of scales (BF-522W, Tanita,
Japan) and body mass was adjusted for fluid loss and expressed as a percentage change.

Blood collection
Upon arrival at the laboratory, participants rested for 20 min before blood collection was
performed. Blood was drawn in a seated position 10 min before and 10 min after each HST
via a 22g needle from a prominent superficial forearm vein located at the antecubital fossa,
and drained directly into an 8.5 ml sterile serum separator Vacutainer tube containing a clot
activator and gel for serum separation (Beckton and Dickson, USA). Samples were
refrigerated at 4°C for 30 min to allow clotting and then centrifuged at 1000 x g at 6°C for 10
min (Rotina 420R, Hettich, Germany). Serum was removed and stored in 400 µl aliquots that
were frozen immediately for a maximum of three months at -80°C for later analysis. Serum
concentrations of IL-6 (Quantikine HS600B, R&D Systems, United States), IgM (AB137982,
Abcam PLC, United Kingdom), and LPS (HIT302, Hycult, Biotechnology, Netherlands)
were analysed in duplicate by ELISA according to manufacturer’s instructions.

Aerobic Interval Training
Participants in HOT and NEUTRAL undertook matched aerobic interval training on a cycle
ergometer (Monark Ergomedic 828 E, Sweden) in hot and humid (35°C and 70% RH) or
thermo-neutral conditions (20°C and 50% RH) respectively. The exercise-training
intervention included seven training sessions comprised a standardised 3 min warm-up
followed by 4 x 10 min interval at a fixed workload of 55% $\dot{V}O_2_{\text{max}}$. A three min rest period
was given between each workload and water consumed ad libitum. A shorter duration
interval-based protocol was chosen to better reflect the training status of the recreationally-
tained participants; interval-based training has been shown to be beneficial for heat
acclimation (Dawson et al. 1989; Kelly et al. 2016), and shorter duration training can reduce
cumulative fatigue (Wingfield et al. 2015) while promoting performance (Nielsen et al 1997).
Heart rate was recorded at 5 sec intervals and RPE and TComf recorded at the end of each interval. Participants self-reported symptoms of illness, inflection, soreness or inflammation prior to the start of each training session. No symptoms of illness or infection were reported.

***Figure 1 about here***

Statistical Analysis

Data that passed tests for homogeneity of variance were analysed by a mixed-model analysis of variance or t-test (where appropriate) and significance accepted when \( p \leq 0.05 \). Where significant differences were indicated they were identified with the post hoc Tukey Test. Data is expressed as mean ± SD and change scores expressed as mean ± 90% confidence limits (CL). The baseline TT performance (s) was not normally distributed and therefore analysis of covariance was used to investigate between-group differences with participant \( \dot{V}O_2 \) max employed as the covariate - TT results are expressed as adjusted mean ± SD or 90% CL where appropriate. Standardised effect sizes (ES) were calculated to indicate the magnitude of change and/or difference within- and between-groups. The criteria to interpret the magnitude of ES were: <0.2 trivial, 0.2-0.6 small, 0.6-1.2 moderate, 1.2-2.0 large, and >2.0 very large (Hopkins, 2004).

Determination of biomarker concentrations and curve fit analysis was performed using GraphPad Prism Version 6.03 (GraphPad Software Inc, United States) according to the manufacturer’s instructions. The manufacturer stated intra-assay precision was <10% for all assays. Statistical analyses were performed in IBM SPSS Statistics Version 22 (IBM, United States). Power analysis was conducted prior to the study and a minimum of eight participants was deemed sufficient to detect the smallest worthwhile change between means assuming the reference change in 5 km time trial performance was approximately twice the magnitude of the typical error of measurement, with a Type I error of 5% and Type II error of 20%.

Results

Heat Stress Test

Between group analyses

At HST3 a significant between-group effect for TT was evident between HOT and CON (HOT was faster by 8.2%, ± 5.2%, 90% CL, \( p = 0.03 \)). Time trial performance is presented in Figure 2 as adjusted means from the analysis of covariance. No significant between-group effects of short-term heat training were observed for \( T_c \) (0.3% ± 0.6%, Figure 3), RPE, TComf, sweat loss, or HR (Table 1).

Within group analyses

Both the HOT and NEUTRAL group significantly improved TT performance in HST2 at the end of the seven days short-duration protocol (after four heat training sessions) compared to HST1, with HOT 33 s ± 20 s (adjusted mean ± 90% CL) faster (\( p = 0.02 \)) and NEUTRAL 39 s ± 18 s faster (\( p = 0.01 \)) than baseline. After conclusion of the post-training top-up period, only HOT had a significant improvement in their TT performance at HST3 compared to HST1, completing the course 45 s ± 25 s faster (\( p = 0.01 \)) compared to their HST1 performance. The performance of HOT in HST3 was also significantly improved from HST2 (12 s ± 7 s, \( p = 0.01 \)).

***Figure 2 about here***
There was a small but significant mean reduction in exercising $T_c$ observed in the HOT group from HST$_1$ to HST$_2$ during the 60% workload of $-0.22 \pm 0.14 \, ^\circ C$ (mean $\pm$ 90% confidence limits, $p = 0.02$, ES = -0.53). Additionally, there was a trend for lower $T_c$ during the 70% workload ($-0.25 \pm 0.21 \, ^\circ C$, $p = 0.06$, ES = -0.53) and during the TT ($-0.25 \pm 0.24 \, ^\circ C$, $p = 0.09$, ES = -0.45). Small-moderate significant reductions in $T_c$ was observed in the HOT group from HST$_1$ to HST$_3$ at the 50%; $-0.18 \pm 0.10 \, ^\circ C$ ($p = 0.016$), 60%; $-0.23 \pm 0.18 \, ^\circ C$ ($p = 0.04$) and 70%; $-0.34 \pm 0.27 \, ^\circ C$ ($p = 0.05$) workloads. The HOT group also experienced a small reduction in peak $T_c$ during HST$_2$ compared to HST$_1$; $-0.25 \pm 0.21 \, ^\circ C$ ($p = 0.057$), see Figure 3a. Neither the NEUTRAL nor the CON group experienced meaningful reductions in $T_c$ in any of the HST’s (Figure 3b and 3c).

The HOT group exhibited a moderate improvement in thermal comfort in HST$_3$ compared to HST$_1$ ($p < 0.01$). Thermal comfort was also improved in HOT during HST$_2$ and HST$_3$ compared to NEUTRAL ($p = 0.04$ and $p = 0.03$, respectively). There were no meaningful within group reductions of HR during the HST’s (Table 1).

Inflammatory biomarker responses

Between-group analyses
No significant differences between groups in any of the biomarker responses were observed either at rest or in response to any of the three HST’s. Between groups there was a $-8\% \pm 32\%$ difference in post HST IL-6, $-52\% \pm 111\%$ in LPS, and $-35\% \pm 36\%$ in IgM.

Within-group analyses
There was a large to very large ($\sim 4 \pm 2$ fold) rise in serum IL-6 concentration for all groups following each HST. Serum concentrations of IgM and LPS were not substantially different following the HST for each group and there were no significant time interactions observed in any group. However, there was a trend for a small reduction in post-exercise concentrations of IgM in all participants (n=24) following the first HST ($p = 0.08$, ES = 0.40). There were no within-group changes observed in serum concentration of LPS (44% $\pm$ 208%) or IgM (6% $\pm$ 61%) neither pre nor post each HST. Blood biomarker concentrations are presented in Figure 4.

*Figure 4 about here***

Training sessions
There were no within-group changes observed in exercising heart rate during each of the training sessions for the HOT or NEUTRAL groups. Although the HOT group exhibited higher HR in all training sessions compared to NEUTRAL, Table 2 outlines the physiological and perceptual variables collected during the interval training sessions.

***Table 2 about here***

Discussion
Short term heat training followed by supplementary top-up sessions (seven training sessions over 18 days) improved time trial cycling performance, reduced exercising core temperature, and improved thermal comfort during a strenuous cycling task in the heat. In contrast, participants in the thermo-neutral (exercise) and control conditions did not experience these physiological and perceptual improvements. However, as the thermo-neutral group also improved their 5km TT performance after the initial short-term block of heat-training (5 training session in seven days), it is likely a greater stimulus in terms of intensity and duration is required to elicit greater gains from heat training in shorter time periods. Although mean IL-6 concentration increased four-fold following each HST, the exercise stimulus did not elevate other biomarkers of systemic inflammation such as IgM and LPS. As biomarker activity was largely unaffected by short-term heat training, as evidenced by IL-6 returning to basal level prior to each HST, it appears that it is possible to gain useful performance and thermoregulatory adaptations from short-duration training without compromising the immune system. Therefore, coaches and athletes can use short-term heat acclimation training coupled with supplementary heat training sessions to improve time trial performance, in the confidence there is little likelihood of impairing immune system functionality.

Improvements in time trial performance with short-term heat training have been reported by Lorenzo et al. (2010) in cycling and Garrett et al. (2012) in rowing. However Garrett and colleagues did not include a control group undertaking matched training over the five day heat training program. It is possible that the improvement (4 s) observed in 2000 m rowing time in that study could have been similar to that of an exercise alone control/placebo group.

In our study the effects of heat training were largely similar to that of the exercise-alone group during the first week of training. However the supplementary top-up sessions appeared to elicit further gains, indicating that while short term training offers some benefits a longer program offers additional benefits. In the study by Lorenzo and colleagues, one third of the experimental group (four out of twelve) were participants who had already completed the control condition of the experiment, consequently, the pre-exposure to exercise in the heat and heat stress test protocols. This prior exposure may have conferred a small degree of acclimation prior to taking part in the experimental portion of that study. In the present study, the inclusion of both an exercise matched (NEUTRAL) and control (CON) group allows clear interpretation of whether the heat acclimation training was responsible for the reported changes in performance and physiological adaptations. Adaptations and improvements reported previously (Lorenzo et al. 2010; Garret et al. 2012) may relate to the increased frequency of training within a given training period. It is likely that the heat exposure resulted in ergogenic performance and thermoregulatory adaptations at the end of the 18 day period beyond that of exercise training alone.

The improved time trial performance by participants in HOT was matched by those in NEUTRAL at HST₂, indicating that the stimulus for performance gain over 7-days of short-duration training in moderately-trained individuals is exercise per se rather than the environmental conditions under which it is performed (i.e. hot or neutral). Although, there were additional performance gains for the HOT group after the three supplementary training sessions over 10 days which increased HOT’s total heat load to nine exposures (two HST’s and seven training sessions, approx. nine hours). Clearly, exercise in temperate conditions results in heat production which elevates body temperature (Gleeson, 1998), and among recreationally-active participants it seems probable that this heat production is a sufficient stimulus to generate modest adaptations over seven days. The observation of continued adaptation and performance improvement only in the HOT group after the post-training top-up period (after the full 18 days) suggests that the generic adaptive responses experienced by NEUTRAL after seven days had most likely run their course and plateaued. As this study
recruited participants that were recreationally-active it is possible that elite endurance
athletes, already well-accustomed to performing regular heat producing exercise would
differentially experience greater gains compared to a matched neutral exercising group,
although this remains to be determined.

Although a greater number of heat exposures (than imposed in this study) could yield more
substantial physiological adaptations and performance improvements, it is also possible that
this increase could trigger systemic inflammation (Lim et al. 2009). The ~4 fold increase of
IL-6 concentration in all participants after the HST may not signify heat stress per se, but
rather the stress invoked by the exercise demand itself. IL-6 can be released into the
circulation following various pathological events such as physical exercise, trauma, sepsis,
and thermal injury (Moldoveanu et al. 2000; Natelson et al. 1996). There are few studies that
have investigated IL-6 as a blood biomarker during exhaustive exercise in the heat, although
one study reported a very large increase in IL-6 following 2 h of exhaustive walking in
protective clothing at 40°C (Selkirk et al. 2008). However, a different study reported a very
large increase in IL-6 following 3 h of exercise at 60-65% of V\textsubscript{O}2peak in typical laboratory
conditions (Moldoveanu et al. 2000). Prolonged elevation of IL-6 may signify cumulative
fatigue or a neuroinflammatory response (Vargus et al. 2014), however in the present study
IL-6 returned to basal concentration prior to each HST. It appears the training load was
adequate to elicit some physiological and performance benefits over the 18 day period, but
not enough to elicit wider systemic or prolonged inflammation. Although IL-6 appeared to be
the most sensitive blood biomarker to the exercise task, its usefulness in specifically
signifying heat stress or acclimation status is limited given the non-heat specific nature of its
response.

The low concentrations of LPS observed in this study indicates the participants tolerated the
moderate-high heat load that was presented to them, and in doing so experienced minimal gut
leakage (Pyne et al. 2014). As LPS is the primary endotoxin translocated to circulation under
heat load (Yeh et al. 2013), its concentration and regulation is a primary consideration in
study of responses to the heat. It appears that undertaking ~40 min of strenuous exercise in
the heat is not sufficient to evoke a systemic inflammatory response in healthy moderately
active individuals. Furthermore, as IgM is a key antibody in neutralising LPS (Camus et al.,
1998), its concentration in circulating blood can reflect the body’s response to endotoxin
accumulation and as protection against further challenges. In this study the pre- to post-
exercise change in IgM concentration in the heat was not significant, however following the
first HST there was a trend (p= 0.08) towards reduced concentrations in all participants. It is
likely that a substantial heat and/or exercise stimulus may be required for IgM concentrations
to be substantially affected, although in this case it seems possible that there was some
degradation of the antibody occurring. Although some between changes were observed in
LPS and IgM concentrations (~44% and ~35% respectively) there was substantial uncertainty
in these estimates due to high variability in the biomarker response. Only one other study has
investigated the response of non-specific IgM following exercise in hot and humid conditions
(Hailes et al. 2011). During that study a 20% increase of plasma IgM was reported pre- to
post-exercise at day one of the heat acclimation program, this change was not present at day
five, with post-exercise IgM not varying from basal levels. The initial change of IgM in
Hailes and colleagues’ study may relate to the participants required to reach a terminal core
temperature of 39.5 °C, whereas in the present study core temperatures did not consistently
rise to that level. Despite a substantial exercise and heat load (60 min HST), participants in
the present study were able to cope with the demands of the exercise task with limited
inflammation and immune disturbances.
Conclusions

Short-term heat training with the addition of supplementary top-up training sessions over 18 days enhanced time-trial performance by \( \sim 9\% \) in recreationally-active healthy adults, although thermo-neutral exercise training alone was a sufficient stimulus for performance gains of \( \sim 6\% \) over seven days. The effects of heat training appear to become more worthwhile between 7-18 days. Nevertheless, training in either the heat or neutral conditions proved beneficial to performance and thermoregulatory responses compared to a control (non-exercise) condition. However, none of the experimental groups exhibited substantial changes in LPS, IgM, or IL-6 indicating the training and heat load did not elicit an immune response. It is possible that a more intense heat training protocol may lead to greater physical and immune responses.

Conflict of interest:
The authors declare no conflicts of interest and this project was funded from internal funds.

Acknowledgment:
The authors would like to thank the participants and the laboratory staff for their time and cooperation throughout this demanding study.

Author Contributions
JG, DP, GD, CM, and AE contributed to the study design. JG completed data collection and conceptualization and drafting of the article. JG and KM completed Biomarker analysis. All authors performed all data analysis and conceptualizing and revising the study critically for important intellectual content, and approved the final manuscript.

Data are expressed as mean ± SD. HOT = Heat training group, NEUTRAL = Thermo-neutral training group, CON = Control group. HR = Heart rate. Sweat loss (%) is expressed as the amount of sweat lost (kg) divided by the persons pre-exercise mass (kg) x 100. RPE_{Avg} and TComf_{Avg} are the mean Rating of Perceived Exertion and Thermal Comfort rating across the entire Heat Stress Test (HST). RPE_{End} and TComf_{End} represent the values recorded at the cessation of the HST. *Significantly different from HST₁. †Significantly different from HST₂. °Significant difference between HOT and NEUTRAL. ΩSignificant difference between HOT and CON.

Data is expressed as mean ± SD. HOT = Heat training group, NEUTRAL = Thermo-neutral training group. TR₁ = Training session on day one, TU₃ = Top up training session on day 15. HR = Mean heart rate across four x 10 minute intervals. RPEAvg and TComfAvg are the mean Rating of Perceived Exertion and Thermal Comfort rating across the training session. * Significantly different from TR₁. † Significantly different from TR₄. * Significantly different between HOT and NEUTRAL.
